***Abstract*—**

I. Finding access_to_the_peanut_cave

Our docker image for access_to_the_peanut_cave is located at:

The challenge binary is:

The solution is at:

Hashes obtained using linux md5sum:

The hash for the binary is:

The hash for the source file is:

II. Introduction

access_to_the_peanut_cave is a challenge binary that leverages multiple types of challenges as locks that an attacker has to break through in order to launch a shell. In order to solve these locks an attacker must have knowledge of randomization in C, linux file read conventions, and buffer overflows. In this work we explain our challenge binary *access_to_the_peanut_cave* cave as well as providing details on how to exploit it.

III. Design

access_to_the_peanut_cave is a binary which involves a series of three challenges that need to be correctly completed in order to enter the secret peanut cave. The inner part of the cave gives great power to anyone who can reach it (launch */bin/shh* using execve to gain privilege escalation for instance). The main idea of this challenge is to show that implementing a serie of weak protection is not enough to secure a program. On top of the protections added to this binary, the stack canaries and ASLR are enabled.

The three locks are the following:

- **Random password:** To enter the inner room, the user have to enter the good password. By design, the password should be random since generated by the *rand()* funciton.
- **File IO:** To even enter the password, the user need to point the program to the right input.
- **No arbitrary execution:** The executed instruction depends of the value used to select the way to enter the password. Therefore, the user shouldn't by able to execute arbitrary instrucition.

A. Lock 1: Random password

Our first lock was inspired by a CTF binary challenge named *random* on pwnable.kr. In *access_to_the_peanut_cave* we ask for a key and then perform an *XOR* with a key that we "randomly" generated using the rand function and compare it to the value `0x9000ddo9` (goood dog).

The core of the vulnerability comes from our incorrect usage of the *rand()* function. We forgot to actually seed our random function! As a result, it will be given the default seed of 0. This means that we can easily create a separate script that calls rand the same way, and gets the same "random" number. This will allow us to get the correct value to open this lock.

B. Lock 2: File IO Lock

Our second lock was inspired by a CTF binary challenge named *fd* on pwnable.kr. This lock uses an argument passed to the main function, and subtracts a particular key from it before utilizing it as the file descriptor for a read operation. The trick to this lock is that if the read function is passed a file descriptor of 0, it will read from stdin by default. This will then allow the attacker to input the correct password to access execve.

C. Lock 3: Time of Check, Time of Use Lock

Our third lock was our own design to utilize a classic buffer overflow to overwrite a value before it is used. In this case, we call *execve()* with the values of *buffer2* (which is set to be the same as *argv[1]*). However, *argv[1]* was utilized early in the program and needed to be set to a particular value in order to pass lock 2. Not a problem! We have a *gets()* call on a buffer allowing for a buffer overflow. This allows us to overflow into *buffer2* and set the value to be "/bin/shh" in between when it is used to open lock 2, and when it is used in our third lock to call *execve()*.

IV. Implementation

The following steps must be followed to get privilege escalation:

1) Compile the code with: `gcc -o access_to_the_peanutcave_reboot access_to_the_peanutcave_reboot.c`.

Note that we do not have to disable any default stack protections such as stack canaries or ASLR.

2) The exploit can be run with this command: `access_to_the_peanutcave_rebot 4660`. This includes the first argument as 0x1234, the value it needs to be to clear the second lock.
3) On the first prompt type 4220229742 which will correctly XOR with the random number to provide `0x9000dd09` and unlock the first lock
4) On the second prompt type a padding of size 32 followed by `/bin/shh`, this will overflow `buffer` into `buffer2` and in doing so allow us to pass `/bin/shh` as an argument to execve to launch the shell.

V. Exploitation

Our exploit involves a set of 3 different inputs in order to break each successive lock. The combination of these inputs allows us to break through the three layers of locks in order to launch a shell with privilege escalation.

A. Before program execution

Before the start of program execution there are several steps that need to be taken. First, we must find what the value of random is going to be. The easiest way of doing this is to create a program which simply creates a random number using rand and prints it out. In our case, we used a file called test.c to do this, the code for doing so is in lines 8-10 in our test.c file. Once we get that value (1804289383) we can perform and `XOR` with `0x9000dd0g` from line 26 in our challenge binary (the first lock we need to break) in order to get a value we will need later in execution. That number turns out to be 4220229742.

We will also need to use GDB to disassemble the code in order to grab the locations of *buffer* and *buffer2* so that we can know how much padding we need in order to overflow the correct value into *buffer2* if we don't want to run the program multiple times. Alternatively, we found our padding simply by running the program once with strace and seeing what was passed to *execve()*.

In addition, when we are calling the program we will need to give it an argument equal to *0x1234* (from line 20 of our challenge program) so that eventually when the program grabs a file descriptor, we will have an fd of 0 allowing us to read from stdin and break the second lock.

B. During program execution

When the program is running, the *argv[1]* needs to be equal to 4660 in order to the file descriptor used in the *read()*. Without it, the program will simply stop since there will be no other valid file descriptor number. Otherwise, it continues smoothly.

When the program is running, there will be two prompts. On the first prompt, we have to input the value we got from XORing rand earlier, 4220229742. This will result in the comparison being true, and will open the lock.

After passing the lock, our program is designed to execute the command specified by the first argument, which must be 4660 in order to be able to reach this state. We will need to make sure that *buffer2* is set to be "/bin/shh" instead. In order to do that, we have to do a buffer overflow. We could do that by coming through the disassembly before we begin (as previously stated), however in our case we just supplied an input of "AAAABBBBCCCC..." and then using strace to see what was passed to execve. Using this method we found that we needed a buffer of size 32 before inputting "/bin/shh" (we could also have use gdb to verify how far *buffer* is from *buffer2* on the stack. We then redid our execution and put in out correct buffer and "/bin/shh" on the second prompt. This successfully launches a shell.

VI. Conclusion

In this work we have introduced a new challenge binary access_to_the_peanut_cave, a binary with a series of three locks that can be exploited to launch a shell. We also showed how to exploit this binary by explaining the vulnerabilities in the rand() function in C, the affect of using the read function on a given file descriptor, and how our buffer overflow allows the user to modify sensitive data to launch a shell.
